# Sparse Regression Faster than $d^{\omega}$ 

Mehrdad Ghadiri* ${ }^{*} \quad$ Richard Peng ${ }^{\dagger} \quad$ Santosh S. Vempala ${ }^{\ddagger}$

#### Abstract

The current complexity of regression is nearly linear in the complexity of matrix multiplication/inversion. Here we show that algorithms for 2-norm regression, i.e., standard linear regression, as well as $p$-norm regression (for $1<p<\infty$ ) can be improved to go below the matrix multiplication threshold for sufficiently sparse matrices. We also show that for some values of $p$, the dependence on dimension in input-sparsity time algorithms can be improved beyond $d^{\omega}$ for tall-and-thin row-sparse matrices.

## 1 Introduction

In this paper, we consider the $p$-norm regression problem. This can be stated in two essentially equivalent ways. The input consists of a matrix $A \in \mathbb{R}^{n \times d}$ and a vector $b \in \mathbb{R}^{n}$.

1. $\min \|A x-b\|_{p}^{p}, n \geq d$.
2. $\min _{A x=b}\|x\|_{p}^{p}, n \leq d$.

The case of $p=2$ is classical linear regression, widely used in machine learning [34] and optimization [5]. Over the past two decades, regression in other norms has become increasingly popular in practice [7, 16], and also recently found to be useful as an algorithmic primitive [22, 21].

The complexity of the first version ( $\ddagger$ has been shown to be $\tilde{O}\left(n n z(A)+d^{\omega}\right)$ for $p=2[24,10]$ and also for $p$ in a constant range around 2 , namely $p \in\left[\frac{2 \omega-2}{2 \omega-3}, 2 \omega-2\right]$ [6]. For the second version (q), the best known complexity is $\tilde{O}\left(p d^{\omega}\right)$ [2, 1]. For all these algorithms, the bottleneck for improving the complexity is the time to solve a single linear system, which is currently $\tilde{O}\left(d^{\omega}\right)$ for a $d \times d$ linear system. Recent progress on linear systems [25] shows how to solve sufficiently sparse linear systems faster than $d^{\omega}$, i.e., with asymptotic complexity that grows as a power of $d$ strictly smaller than $\omega$. This raises the possibility of faster algorithms for $p$-norm regression. However, since these algorithms either make multiple calls to a linear system solver, or perform other amortizations to maintain a solution to a linear system solver, the improvements in solving linear systems for sparse matrices are not automatically transferred to these optimization problems.

In this paper, we show that all the state-of-the-art results for $p$-norm regression which are currently bottlenecked at $d^{\omega}$ can be improved, going below the matrix multiplication threshold, for sufficiently sparse matrices.

To state our results, we use the notation $n n z(A)$ to denote the number of nonzeros entries of $A$ and $n n z_{d}(A)$ to denote the maximum number of nonzero entries in any $d$ rows of an $n \times d$ matrix $A$.

We begin with linear regression. The following result of [8, 24, 10] shows how to solve this problem in input-sparsity time up to a $d^{\omega}$ term.

Theorem 1 (Input Sparsity Time Linear Regression, Clarkson-Woodruff '13 [8]). The linear regression problem $\min \|A x-b\|_{2}^{2}$ can be solved to within relative error $1+\epsilon$ in time $\tilde{O}\left(n n z(A)+d^{\omega}\right)$ where $d$ is the rank of $A$.

Our first theorem shows that for sparse matrices, we can go below the $d^{\omega}$ threshold and maintain input sparsity time.

[^0]Theorem 2. [Sparse Linear Regression] Let $A \in \mathbb{R}^{n \times d}$, where $n \geq d$, be a matrix with condition number $\kappa$. Let $x^{*}=\arg \min \|A x-b\|_{2}^{2}$. There is an algorithm that finds $\bar{x}$ such that

$$
\|A \bar{x}-b\|_{2}^{2} \leq(1+\epsilon)\left\|A x^{*}-b\right\|_{2}^{2}
$$

in time

$$
\tilde{O}\left(\left(n n z(A)+n n z_{d}(A)^{\frac{\omega-2}{\omega-1}} d^{2}+d^{\frac{5 \omega-4}{\omega+1}}\right) \log ^{2}(\kappa / \epsilon) \log \left(\frac{\kappa\|b\|_{2}}{\epsilon O P T}\right)\right)
$$

with probability at least $1-\tilde{O}\left(d^{-10}\right)$.
We note that the theorem gives an improvement in the complexity of linear regression to $n n z(A)+o\left(d^{\omega}\right)$ for matrices that have $o\left(d^{\omega-2}\right)$ nonzeros in each row (or $o\left(d^{\omega-1}\right)$ entries in any $d$ rows). Moreover, these improvements hold for any value of $\omega>2$. If each row has $O(1)$ entries, then the runtime with the current value of $\omega$ is bounded by $d^{2.331645}$ up to logarithmic terms.

We next turn our attention to $p \neq 2$, starting with $p$ close to two. In this setting, [6] used a homotopy method to obtain the following result.
Theorem 3 (Input Sparsity Time $\ell_{p}$-norm Regression, Bubeck-Cohen-Li-Lee '18 [6]). Let $1<p<\infty$. The problem $\min \|A x-b\|_{p}^{p}$ can be solved to within relative error $(1+\epsilon)$ in time $\tilde{O}\left(n n z(A)+d^{\omega}+d^{0.5 \max \left\{p, \frac{p}{p-1}\right\}+1}\right)$.

We show that using a sparse inverse operator improves the time complexity for sparse matrices.
Theorem 4. [Sparse $p$-norm, $p$ near 2] Let $A \in \mathbb{R}^{n \times d}$, where $n \geq d$, be a matrix with condition number $\kappa$. Let $x^{*}=\arg \min \|A x-b\|_{p}^{p}$. There is an algorithm that finds $\bar{x}$ such that

$$
\|A \bar{x}-b\|_{p}^{p} \leq(1+\epsilon)\left\|A x^{*}-b\right\|_{p}^{p}
$$

in time

$$
\tilde{O}\left(\left(n n z(A)+d^{0.5 \max \left\{p, \frac{p}{p-1}\right\}+1}+n n z_{d}(A)^{\frac{\omega-2}{\omega-1}} d^{2}+d^{\frac{5 \omega-4}{\omega+1}}\right) \log ^{2}(\kappa / \epsilon) \log \left(\frac{\kappa\|b\|_{2}}{\epsilon O P T}\right)\right),
$$

with probability at least $1-\tilde{O}\left(d^{-10}\right)$.
The above theorem gives improvements for $\frac{2 \omega-2}{2 \omega-3}<p<2 \omega-2$ and matrices that have $o\left(d^{\omega-2}\right)$ nonzeros in each row.

Finally we turn to arbitrary $p>2$. Note that for this general setting, obtaining input sparsity algorithms is an open problem. The most general and efficient result is that of [2], which builds on [1].
Theorem $5\left(\ell_{p}\right.$-Norm Regression in Matrix Mutliplication Time, Adil-Kyng-Peng-Sachdeva '19 [1, 2]). The $p$-norm regression problem of the form $\min _{A x=b}\|x\|_{p}^{p}$ can be solved in time $\tilde{O}\left(p\left(d^{\omega}+d^{7 / 3}\right)\right)$ to high accuracy.

Theorem 6. [Sparse general p-norm] Let $2<p<\infty$. Let $A \in \mathbb{R}^{n \times d}$, where $n \leq d$, be a matrix with condition number $\kappa$. Let $x^{*}=\arg \min _{A x=b}\|x\|_{p}^{p}$. Let $m<d^{1 / 4}$ be the number of blocks in the block Krylov matrix used by the sparse linear system solver. There is an algorithm that finds $\bar{x}$ such that $A \bar{x}=b$ and

$$
\|\bar{x}\|_{p}^{p} \leq(1+\epsilon)\left\|x^{*}\right\|_{p}^{p}
$$

in time

$$
\tilde{O}\left(\left(n n z(A) \cdot d \cdot m^{\frac{(p+2)}{(3 p-2)}}+d^{2} \cdot m^{3+\frac{(p-2)}{(3 p-2)}}+d^{2+\frac{p-(10-4 \omega)}{3 p-2}}+d^{\omega} m^{2+\frac{(p-2)}{(3 p-2)}-\omega}\right) d^{o(1)}(p \log p) \log ^{2}(\kappa / \epsilon) \log \left(\frac{\kappa\|b\|_{2}}{\epsilon O P T}\right)\right)
$$

with probability at least $1-\tilde{O}\left(d^{-10}\right)$.
For $\omega>\frac{7}{3}$ and $p>2,2+\frac{p-(10-4 \omega)}{3 p-2}<\omega$. Moreover, by choosing $m$ to be a suitably small power of $d$, and noting that the exponent of $m$ in the last term with the $d^{\omega}$ factor is negative, we can ensure that the overall complexity is $d^{\theta}$ for some $\theta<\omega$. We note that for $1<p<2$, we can instead solve the dual problem for $\frac{p}{p-1}$ norm - see Section 7.2 of [1] if $1<p<2$ and $\omega>\frac{7}{3}$, then

$$
\frac{p /(p-1)-(10-4 \omega)}{3 p /(p-1)-2}<\omega-2
$$

Figure 1 illustrates the best exponent of $d$ for matrices with $n n z_{d}(A)=O(d)$ and different values of $p \geq 2$ for our algorithms based on BCLL approach [6] (Theorem 4) and AKPS'19 approach [1] (Theorem 6).

Figure 1: The exponent of $d$ for different $p>2$ when $n n z_{d}(A)=O(d)$. The dashed line is based on [1] with our modification on the inverse maintenance and use of sparse inverse solver (Theorem 6). The dotted line is based on [6] with our modification using the sparse inverse solver [25] for the preconditioner (Theorem 4). For all $p>1$, the exponent of $d$ is lower than the current value of $\omega$.

### 1.1 Related Work

$\ell_{2}$ regression, also known as linear regression, is one of the most widely used data analytic tools. The $p \neq 2$ case also occurs throughout optimization, statistics, and machine learning. Earlier works on such algorithms treated them as extensions of the linear case, via convex cones [4.
$\ell_{2}$ regression algorithms that run in time proportional to the smaller dimension, or rank of the matrix, have been studied extensively over the past decade [15, 8, 33. Many of these ideas have been extended to $\ell_{p^{-}}$ norm regression [23], more general norms [9], as well as linear programming. However, $\log (1 / \epsilon)$ dependencies were only obtained very recently via inverse maintenance approaches 32.

Over the past few years, $\ell_{p}$ norm minimization has been a focal point for designing more efficient algorithms. These recent developments are based on a wide range of starting points, including higher order smoothness [17, homotopy methods [6, and generalized preconditioning [1, 2]. Our algorithms are based on combining the latter two methods, which have $\log (1 / \epsilon)$ dependence on approximation error $\epsilon$, with recent developments of fast solvers for sparse linear systems [25].

Our modification of the Bubeck-Cohen-Lee-Li result [6] is based on directly substituting the solver by one tailored for sparse matrices. Our modification of [1] on the other hand requires modifying the inverse maintenance steps in the $\tilde{O}\left(d^{\omega}\right)$ time algorithm from that paper.

Inverse maintenance is a data structural based approach for speeding up optimization algorithms. It hinges upon the observation that the linear systems arising from second-order optimization algorithms are slowly changing. It dates back to the early papers on interior point methods [20, 28, 11], and is also at the core of recent $d^{\omega}$-time optimization algorithms [12, 29, 32, 19, 18, 31, 30. The main difference between the algorithm of [1] and the linear programming ones is that the total relative change per step is bounded in 3 -norm instead of 2 -norm, Our final performance there also requires opening up the inverse maintenance steps, and directly associating the size of the update maintained with the cost of solving.

The $\ell_{\infty}$ and $\ell_{1}$ case are closely related to linear programs: solving to $1 /$ poly $(n)$ accuracy is in fact equivalent. It is a very interesting question as to whether the runtime gains here extend to solving linear programs.

### 1.2 Approach and Techniques

Our starting point is the improvement in the complexity of solving linear systems for sufficiently sparse matrices. We emphasize that here (and throughout the paper), our complexities refer to the total bit complexity. In many cases, for numerical algorithms to return reliable results, the size of the bit representations might have to get larger along the way.
Theorem 7 ([25]). Given a sparse $d \times d$ matrix A with max entry-wise magnitude at most 1 , a diagonal $d \times d$ matrix $W$ with entry-wise magnitude at most 1 and $m \leq d^{1 / 4}$, along with $\kappa$ that upper bounds the condition numbers of $A$ and $W$, we can obtain in time

$$
\tilde{O}\left(\left(d \cdot n n z(A) \cdot m+d^{2} \cdot m^{3}+\left(\frac{d}{m}\right)^{\omega} m^{2}\right) \log (\kappa)\right)
$$

a linear operator $Z_{A W} A^{\top}$ such that

$$
\left\|Z_{A W A^{\top}}-\left(A W A^{\top}\right)^{-1}\right\|_{F} \leq \kappa^{-10} n^{-10}
$$

Moreover, for an $n \times r$ matrix $B, Z_{A W} A^{\top} B$ can be computed in time $\tilde{O}\left(\left(r \cdot n n z(A) \cdot m+d^{2} r^{\omega-2}\right) \log (\kappa)\right)$.
In the above theorem, $m$ denotes the number of blocks in the block Krylov space approach used by Peng and Vempala 25. In their main theorem, they choose an $m$ that optimizes the running time of Theorem 7 . However, we need to exploit the flexibility of $m$ in our running times because the cost of low rank updates on matrices with $\tilde{O}(m)$ bits also comes to play. In all of our results, one can see the improvement by setting $m$ to a small polynomial in $d$, e.g., $m=d^{0.01}$. However the best value of $m$ depends on multiple factors including the value of $\omega$ and the sparsity of the matrix.

For brevity of notation, we sometime denote the running time of the sparse linear system solver by $d^{\theta}$. In these cases one can replace $d^{\theta}$ with $\tilde{O}\left(\left(d \cdot n n z_{d}(A) \cdot m+d^{2} \cdot m^{3}+\left(\frac{d}{m}\right)^{\omega} m^{2}\right) \log (\kappa)\right)$.

Since the above statement is a bit more general than the main theorem of [25], we show how their methods easily extend to this version in Section 5

For linear regression, the method of [10], uses a sequence of linear solves to approximate leverage scores, sample the given matrix according to these scores, then applies the Richardson iteration to compute a high accuracy approximation. As we will see, the main ingredient we need is a spectral approximation to the given matrix. The algorithm of [6] also needs spectral approximations of a set of $\tilde{O}(1)$ matrices. To handle both, we introduce the following efficient sparse spectral approximation - see Definition 1 .
Theorem 8. Let $A \in \mathbb{R}^{n \times d}$ such that the condition number of $A^{\top} A$ is $\kappa$. Let $m<d^{1 / 4}$ be the number of blocks in the block Krylov matrix used by the sparse linear system solver. There exists an algorithm that finds a constant-factor spectral approximation $\widetilde{A}$ with $\tilde{O}(d)$ rows of $A$ in time

$$
\tilde{O}\left(\left(n n z(A)+d \cdot n n z_{d}(A) \cdot m+d^{2} \cdot m^{3}+\left(\frac{d}{m}\right)^{\omega} m^{2}\right) \cdot \log ^{2}(\kappa)\right)
$$

and with a probability of at least $1-\tilde{O}\left(d^{-10}\right)$
Finally, for general $p$, the algorithm of [1, 2] is more complicated. When $p$ is large, it first reduces the $p$-norm regression problem to a small number of $q$-norm regression problems for $q=O(\sqrt{\log d})$. The latter problem is reduced to a sequence of 2 -norm regression problems. It would be too expensive to solve each one individually. So they maintain an efficient preconditioner, and in each iteration solve the new problem by first using the preconditioner, then running a Richardson's iteration to get a high accuracy solution. To maintain the preconditioner efficiently, they use the Sherman-Morrison-Woodbury formula, but the updates happen only when the changes are "significant" as determined by the rank of the update, and a bucketing strategy. The amortized cost of their approach, per iteration, really is $d^{\omega-(1 / 3)}$, with $d^{1 / 3}$ iterations overall.

To improve on this, we want to use the sparse inverse. However, the theorem of [25] gives an inverse operator in the form $Z_{A^{\top} A}$ that involves matrices with $O(m \log (\kappa))$ bits. Thus, naively applying the Woodbury formula could be too expensive, resulting again in runtime that grows as $d^{\omega}$. To get around this, we set a threshold for the rank of the update. We compute the sparse inverse entirely from scratch every $(d / m)^{1 / 3}$ iterations. This ensures that the rank of the update is at most $d / m$. This reduces the cost of the Woodbury update to below $d^{\omega}$ using fast rectangular matrix multiplication, in spite of $m$ bits per entry. These ideas are described precisely in Section 4.

### 1.3 Organization

In the next section, we review some definitions, notations, and preliminary results needed for the rest of the paper. In Section 3.1, we improve the running time of finding a spectral approximation with $\tilde{O}(d)$ rows for an $n \times d$ matrix using the sparse linear system solver from [25]. We then use this in Section 3.2 to improve the running time of linear regression $(p=2)$ for $(\rrbracket)$. In Section 3.3 , we consider ( $\ddagger$ ) with a general fixed $p$. This again needs the fast algorithm to find an spectral approximation. In Section 4 , we descrive the algorithm for solving general p-norm regression (2). Finally, in Section 5, we explain how we access the sparse inverse operator and give a proof for Theorem 7 .

## 2 Preliminaries

In this section we review tools, notations, and definitions we need for the rest of the paper. We show the $i$ 'th row of a matrix $A$ with $a_{i}$. For a matrix $A \in \mathbb{R}^{n \times d}$ and a set $E \subseteq[n]$, the matrix with rows of $A$ with indices in $E$ is denoted by $A_{E}$. We denote the psedoinverse of a matrix $A$ by $A^{+}$.
Definition 1. For $\lambda \geq 1$, we say $\widetilde{A} \in \mathbb{R}^{t \times d}$ is a $\lambda$-spectral approximation of $A \in \mathbb{R}^{n \times d}$ if,

$$
\frac{1}{\lambda} A^{\top} A \leq \widetilde{A}^{\top} \widetilde{A} \leq A^{\top} A
$$

A spectral approximation of a matrix is useful because it can be used as a preconditioner to solve linear regression problems.

Lemma 9 (Richardson's iteration with preconditioning [27]). Given a matrix $M$ such that $A^{\top} A \leq M \leq \lambda \cdot A^{\top} A$ for some $\lambda \geq 0$. Let $x^{(k+1)}=x^{(k)}-M^{-1}\left(A^{\top} A x^{(k)}-A^{\top} b\right)$. Then we have

$$
\left\|x^{(k)}-x^{*}\right\|_{M} \leq\left(1-\frac{1}{\lambda}\right)^{k}\left\|x^{(0)}-x^{*}\right\|_{M}
$$

where $x^{*}=\arg \min _{x}\|A x-b\|_{2}^{2}$.
A useful tool to find a small-sized spectral approximation of a matrix is the concept of statistical leverage scores.

Definition 2. The leverage score of the $i$ 'th row $a_{i}^{\top}$ of a matrix $A$ is $\tau_{i}(A)=a_{i}^{\top}\left(A^{\top} A\right)^{+} a_{i}$. The generalized leverage score of $i$ 'th row with respect to $B \in \mathbb{R}^{n^{\prime} \times d}$ is

$$
\tau_{i}^{B}(A)=a_{i}^{\top}\left(B^{\top} B\right)^{+} a_{i}
$$

Lemma 10 (Random Projection). Let $x \in \mathbb{R}^{d}$. Assume the entries in $G \in \mathbb{R}^{r \times d}$ are sampled independently from $N(0,1)$. Then,

$$
\operatorname{Pr}\left(\|x\|_{2}^{2} \leq\left\|\frac{1}{\sqrt{r(1-\epsilon)}} G x\right\|_{2}^{2} \leq \frac{1+\epsilon}{1-\epsilon}\|x\|_{2}^{2}\right) \geq 1-2 e^{-\left(\epsilon^{2}-\epsilon^{3}\right) r / 4}
$$

Definition 3. We show the running time of multiplying an $r \times s$ matrix by an $s \times t$ matrix with $\mathrm{MM}(r, s, t)$. The exponent of matrix multiplication is denoted by $\omega$. In other words, $d^{\omega}=\mathrm{MM}(d, d, d)$.

## 3 Tall Row-Sparse Regression

In this section, we first show how to find a spectral approximation of a matrix $A$ with $\tilde{O}(d)$ rows. Then we use this to show that linear regression can be solved faster than matrix multiplication. Finally we use this result to find spectral approximations for the $p$-norm regression problem for $p$ close to two.

### 3.1 Spectral Approximation

Our approach to finding a constant-factor spectral approximation of a matrix $A$ is to first find a "good" overestimate of leverage scores of rows of $A$. Lemma 11 clearly demonstrate that if we find a vector of overestimates $u$ such that $\|u\|_{1}=O(d)$, then with $\tilde{O}(d)$ samples from rows of $A$, we can recover a spectral approximation of $A$ with a high probability. Before discussing how to find such a vector of overestimates, we need the following definitions and results.

Definition 4. Let $u \in \mathbb{R}_{\geq 0}^{n}$. Let $\alpha$ and $c$ be positive constants. Let $p_{i}:=\min \left\{1, \alpha \cdot u_{i} c \log d\right\}$. We define the function $\operatorname{SAMPLE}(u, \alpha, c)$ that outputs a random diagonal matrix $S$ where each element $S_{i i}$ is $\frac{1}{\sqrt{p_{i}}}$ with probability $p_{i}$ and zero otherwise.

In order to prove Theorem 8, we show that one can find a good overestimate of leverage scores in $O\left(n n z(A)+d^{\theta}\right)$ time using the following lemma from Cohen et al 10 .
Lemma 11 ( 10 ). Let $0<\mu<1$, and $u$ be a vector of leverage score overestimates, i.e., $\tau_{i}(A) \leq u_{i}$. Let $\mu$ be a sampling rate parameter and let c be a fixed positive constant. Let $S=\operatorname{SamPLE}\left(u, \mu^{-2}, c\right)$. Then $S$ has at most $2\|u\|_{1} \mu^{-2} c \log d$ nonzero entries and $\frac{1}{\sqrt{1+\mu}} S A$ is a $\left(\frac{1+\mu}{1-\mu}\right)$-spectral approximation for $A$ with probability at least $1-d^{-c / 3}-(3 / 4)^{d}$.

The following results are useful.
Lemma 12. For a matrix $A \in \mathbb{R}^{n \times d}, \sum_{i=1}^{n} \tau_{i}(A) \leq d$.
The proof of the following lemma is similar to that of Theorem 3 of [10].
Lemma 13. Let u be a vector of leverage score overestimates. For some undersampling factor $\alpha \in(0,1]$, let $S=\sqrt{3 \alpha / 4} \cdot \operatorname{SAmplE}(u, 9 \alpha, c)$, where $c$ is a constant. Let $\tau_{i}^{S A}(A) \leq v_{i} \leq(1+\beta) \tau_{i}^{S A}(A)$, for all $i \in[n]$, where $\beta \geq 0$. Let $u_{i}^{\prime}=\min \left\{v_{i}, u_{i}\right\}$. Then with a probability of $1-d^{-c / 3}-(3 / 4)^{d}, u_{i}^{\prime}$ is a leverage score overestimate, for all $i \in[n], \sum_{i=1}^{n} u_{i}^{\prime} \leq \frac{3 d(1+\beta)}{\alpha}$, and the number of nonzeros of $S$ is $O\left(\alpha\|u\|_{1} \log d\right)$.
Proof. Let $S^{\prime}=\frac{1}{\sqrt{3 \alpha / 4}} S$. Note that the number of nonzeros of $S$ and $S^{\prime}$ are equal. By Lemma 11 , $\frac{1}{\sqrt{1+1 /(3 \sqrt{\alpha})}} S^{\prime} A$ is a $\left(\frac{\sqrt{1+1 /(3 \sqrt{\alpha})}}{\sqrt{1-1 /(3 \sqrt{\alpha})}}\right)$-spectral approximation of $A$ and $S^{\prime}$ has at most $18 \alpha c\|u\|_{1} \log d=O\left(\alpha\|u\|_{1} \log d\right)$ with a probability of at least $1-d^{-c / 3}-(3 / 4)^{d}$. Therefore with a probability of $1-d^{-c / 3}-(3 / 4)^{d}$,

$$
\frac{1}{(1+1 /(3 \sqrt{\alpha}))(3 \alpha / 4)} A^{\top} S^{2} A=\frac{1}{1+1 /(3 \sqrt{\alpha})} A^{\top}\left(S^{\prime}\right)^{2} A \leq A^{\top} A
$$

Now note that $(1+1 /(3 \sqrt{\alpha}))(3 \alpha / 4) \leq 1$ for $\alpha \in(0,1]$. Therefore $A^{\top} S^{2} A \leq A^{\top} A$. Hence, for all $i \in[n]$, $\tau_{i}(A) \leq \tau_{i}^{S A}(A)$. Therefore with a probability of $1-d^{-c / 3}-(3 / 4)^{d}$, for all $i \in[n], u_{i}^{\prime}$ is a leverage score overestimate.

Now we bound $\sum_{i=1}^{n} u_{i}^{\prime}$. Note that $\operatorname{Sample}(u, 9 \alpha, c)$ and $\operatorname{Sample}(\alpha u, 9, c)$ are equal in distribution. Therefore by Lemma 11 . $S^{\prime} A$ is a $\frac{1}{\sqrt{4 / 3}}$-spectral approximation of $A$ with probability of $1-d^{-c / 3}-(3 / 4)^{d}-$ note that this does not add to the probability of failure because one of $1 / \sqrt{4 / 3}$ and $\left(\frac{\sqrt{1+1 /(3 \sqrt{\alpha})}}{\sqrt{1-1 /(3 \sqrt{\alpha})}}\right)$ is smaller than the other one and we can use the probability of success of the tighter bound which would imply the other one. Therefore

$$
\frac{1}{2} A^{\top} A \leq \frac{3}{4} A^{\top}\left(S^{\prime}\right)^{2} A=\frac{1}{\alpha} A^{\top} S^{2} A
$$

Hence, for all $i \in[n]$ such that $a_{i} \perp \operatorname{ker}(S A)$,

$$
\tau_{i}^{S A}(A) \leq \frac{2}{\alpha} \tau_{i}(A)
$$

Now we have

$$
\sum_{i=1}^{n} u_{i}^{\prime}=\sum_{i=1}^{n} \min \left\{u_{i}, v_{i}\right\}=\sum_{i=1}^{n} v_{i} \leq \sum_{i=1}^{n}(1+\beta) \tau_{i}^{S A}(A) \leq \sum_{i=1}^{n}(1+\beta) \frac{2}{\alpha} \tau_{i}(A) \leq \frac{2 d(1+\beta)}{\alpha}
$$

where the last inequality follows from Lemma 12 .

Now, we are equipped to give a high-level view of our algorithm and prove Theorem 8. The high-level description of the algorithm is as the following.

1. Start from the vector of overestimates $u=\overrightarrow{1}$.
2. Repeat the following process for $\log (n / d)$ iterations.
(a) Sample $\tilde{O}(d)$ rows from $A$ based on the vector of overestimates $u$ to form $\bar{A}$.
(b) Update the vector of overestimates of leverage scores using $\bar{A}$, i.e.,

$$
u_{i} \leftarrow a_{i}\left(\bar{A}^{\top} \bar{A}\right)^{+} a_{i}
$$

3. Return $\tilde{O}(d)$ rows of $A$ sampled based on $u$.

We use Lemma 13 and choose our parameters so that in each iteration of this algorithm, we cut the $\ell_{1}$ norm of $u$ by a half. So after $\log (n / d)$ iterations, the $\ell_{1}$ norm of $u$ is about $d$ which means $u$ is a good vector of overestimates of leverage scores. If we perform step (b) of the algorithm naively, then the cost of each update is $d^{2}$ and total cost of each iteration is $n d^{2}$. However one can use random projection to do such updates more efficiently.

Proof of Theorem 8. We show Algorithm 1 finds a spectral approximation in time $O\left(n n z(A)+d^{\theta}\right)$. The technique follows that of Cohen et al [10] that finds the leverage scores of a matrix in a recursive fashion by updating the overestimates. We first prove the correctness of the algorithm assuming that all the randomized steps have succeeded. We then analyze the running time. Finally we bound the failure probability.

Correctness. Algorithm 1 starts with a vector of leverage score overestimates $u^{(0)}=\mathbb{1}_{[n]}$. Therefore $\left\|u^{(0)}\right\|_{1}=n$. To compute the generalized leverage scores we need to compute the following

$$
\begin{aligned}
a_{i}^{\top}\left(\left(S^{(i)} A\right)^{\top}\left(S^{(i)} A\right)\right)^{+} a_{i} & =a_{i}^{\top}\left(\left(S^{(i)} A\right)^{\top}\left(S^{(i)} A\right)\right)^{+}\left(\left(S^{(i)} A\right)^{\top}\left(S^{(i)} A\right)\right)\left(\left(S^{(i)} A\right)^{\top}\left(S^{(i)} A\right)\right)^{+} a_{i} \\
& =\left\|\left(S^{(i)} A\right)\left(\left(S^{(i)} A\right)^{\top}\left(S^{(i)} A\right)\right)^{+} a_{i}\right\|_{2}^{2}
\end{aligned}
$$

We compute the pseudo-inverse using Theorem 7. By Lemma 10 and Theorem 7, we have

$$
\begin{aligned}
\left\|\left(S^{(i)} A\right)\left(\left(S^{(i)} A\right)^{\top}\left(S^{(i)} A\right)\right)^{+} a_{i}\right\|_{2}^{2} & \leq\left(1+\frac{1}{n^{9}-1}\right) \frac{1}{0.9 r}\left\|G\left(S^{(i)} A\right) Y^{(i)}\left(Z^{(i)}\right)^{\top} a_{i}\right\|_{2} \\
& \leq\left(1+\frac{1}{n^{8}}\right)\left(\frac{11}{9}\right)\left\|\left(S^{(i)} A\right)\left(\left(S^{(i)} A\right)^{\top}\left(S^{(i)} A\right)\right)^{+} a_{i}\right\|_{2}^{2} \\
& \leq 2\left\|\left(S^{(i)} A\right)\left(\left(S^{(i)} A\right)^{\top}\left(S^{(i)} A\right)\right)^{+} a_{i}\right\|_{2}^{2}
\end{aligned}
$$

Therefore by Lemma $13, u_{j}^{(i)}$, s are leverage score overestimates and

$$
\left\|u^{(i)}\right\|_{1} \leq \frac{6 d}{12 d /\left\|u^{(i-1)}\right\|_{1}}=\frac{\left\|u^{(i-1)}\right\|_{1}}{2}
$$

as long as $\left\|u^{(i-1)}\right\|_{1} \geq 12 d$. Hence $\left\|u^{(z)}\right\|_{1}=O(d)$ and $u^{(z)}$ is a vector of leverage score overestimates. Thus by Lemma $11, \frac{1}{\sqrt{3 / 2}} S A$ is a 3 -spectral approximation of $A$ with high probability.

Running time. By Lemma 13, $S^{(i)}$ has

$$
O\left(\alpha_{i}\left\|u_{i-1}\right\|_{1} \log d\right)=O\left(\frac{12 d}{\left\|u_{i-1}\right\|_{1}}\left\|u_{i-1}\right\|_{1} \log d\right)=O(d \log d)
$$

nonzeros. Therefore $S^{(i)} A$ has $O(d \log d)$ nonzero rows. Hence $S^{(i)} A$ has $\tilde{O}\left(n n z_{d}(A)\right)$ nonzero entries. Although we want to find an inverse for $\left(S^{(i)} A\right)^{\top}\left(S^{(i)} A\right)$, we do not perform this matrix multiplication because it is too costly. Note that by Theorem 7 , we only need to be able to do matrix-vector multiplication to find the
inverse operator. Note that because the algorithm only has a logarithmic number of iterations, we only need to bound the cost of each iteration. Sampling $S^{(i)}$ given the vector $u^{(i-1)}$ can be done in $O(n)$ time. By Theorem 7 finding the sparse inverse operator $Z_{\left(S^{(i)} A\right)^{\top}\left(S^{(i)} A\right)}$ takes $\tilde{O}\left(\left(d \cdot n n z_{d}(A) \cdot m+d^{2} \cdot m^{3}+\left(\frac{d}{m}\right)^{\omega} m^{2}\right) \log (\kappa)\right)$. By Theorem 7, $M^{(i)}$ can be computed in time $O\left(\left(n n z_{d}(A) \cdot m+d^{2}\right)(\log d+\log (n / d))\right)$ because $G$ has $O(\log d+\log (n / d))$ number of rows. Note that the entries of $M^{(i)}$ only need $\tilde{O}(1)$ bits because the number of bits required for the entries of $Z_{\left(S^{(i)} A\right)^{\top}\left(S^{(i)} A\right)}$ after the multiplication is $\tilde{O}(1)$. Therefore for each $j \in[n]$, the norm $\left\|M^{(i)} a_{j}\right\|$ can be computed in $\tilde{O}\left(n n z\left(a_{j}\right)\right)$, where $a_{j}$ is the $j$ 'th row of $A$. So the leverage score overestimate can be updated in time $\tilde{O}(n n z(A))$ in each iteration. Hence the total running time of the algorithm is

$$
\tilde{O}\left(n n z(A)+\left(d \cdot n n z_{d}(A) \cdot m+d^{2} \cdot m^{3}+\left(\frac{d}{m}\right)^{\omega} m^{2}\right) \log (\kappa)\right)
$$

Failure probability. In each iteration of the for loop in Algorithm 1 there are three sources of randomness: 1) sampling the matrix $S^{(i)}$; 2) the sparse linear system solver to find the inverse of $\left(S^{(i)} A\right)^{\top}\left(S^{(i)} A\right)$; 3 ) and the random JL projection to update the leverage score estimates. We bound the failure probability of each of these steps. Finally, the algorithm samples $S$ and returns $S A$ as the spectral approximation. We bound the failure probability of this step as well.

In each iteration, the probability that $S^{(i)} A$ is not a spectral approximation of $A$ or it does not have $O(d \log d)$ rows is less than $d^{-c / 3}+(3 / 4)^{d}$. The probability that the sparse inverse method cannot does not find an inverse with the desired property is less than $d^{-10}$. By Lemma 10 and the union bound, the probability that the projected vectors (with the Guassian matrix) do not have a norm in the right interval is less than

$$
n \cdot 2 e^{-\left(\epsilon^{2}-\epsilon^{3}\right) r / 4}=n \cdot 2 e^{-(0.01-0.001)(4000 / 9) \cdot(\log d+\log (n / d)) / 4}=2 n \cdot \frac{d}{n} \cdot \frac{1}{d^{11}}=2 d^{-10}
$$

Therefore, with a logarithmic number of iterations, the total probability failure is $\tilde{O}\left(d^{-10}+(3 / 4) d\right)$.

    \(S \leftarrow \frac{1}{\sqrt{3 / 2}} \operatorname{SAMPLE}\left(u^{(z)}, 4, c\right)\)
    return \(S A\)
```

### 3.2 Linear Regression ( $p=2$ )

In the case of linear regression, the idea is to use Algorithm 1 to find a spectral approximation of the matrix and then we can find an inverse of the spectral approximation using Theorem 7. Then we use Richardson's algorithm (Lemma 9) to solve the regression problem. The high-level view of the algorithm is as the following.

1. Find a $\lambda$-spectral approximation $\widetilde{A}$ of the matrix $A$.
2. Set $x \leftarrow \overrightarrow{0}$.
3. Repeat the following for $O\left(\lambda \log \left(\frac{\kappa\|b\|_{2}}{\epsilon O P T}\right)\right)$ iterations.

$$
x \leftarrow x-\left(\lambda \tilde{A}^{\top} \widetilde{A}\right)^{-1}\left(A^{\top} A x-A^{\top} b\right)
$$

For Step 1 of this algorithm, we use Algorithm 1 to find the spectral approximation. We show that this algorithm finds the desired solution.
Proof of Theorem 2. We assume that $\widetilde{A}$ is found using Algorithm 1 and therefore it has $\tilde{O}(d)$ rows. Moreover $M=\lambda \widetilde{A}^{\top} \widetilde{A}$ for the Richardson's iterations. Hence $A^{\top} A \leq M=\lambda A^{\top} \widetilde{A} \leq \lambda A^{\top} A$. Therefore by Lemma 9 , after $k$ steps, we have

$$
\left\|x^{(k)}-x^{*}\right\|_{M} \leq\left(1-\frac{1}{\lambda}\right)^{k}\left\|x^{*}\right\|_{M}
$$

Now we need to show that for the right choice of $k$, we have

$$
\left\|A x^{(k)}-b\right\|_{2}^{2} \leq(1+\epsilon)\left\|A x^{*}-b\right\|_{2}^{2}
$$

To do so, we show that it is enough to pick $k$ such that

$$
\left\|x^{(k)}-x^{*}\right\|_{M}^{2} \leq \epsilon\left\|A x^{*}-b\right\|_{2}^{2}
$$

Note that $A^{\top} b=A^{\top} A x^{*}$. Therefore

$$
\begin{align*}
\left\|A x^{*}-b\right\|_{2}^{2} & =\left(A x^{*}-b\right)^{\top}\left(A x^{*}-b\right)=\left(x^{*}\right)^{\top} A^{\top} A x^{*}+b^{\top} b-2\left(x^{*}\right)^{\top} A^{\top} b=\left(x^{*}\right)^{\top} A^{\top} A x^{*}+b^{\top} b-2\left(x^{*}\right)^{\top} A^{\top} A x^{*} \\
& =b^{\top} b-\left(x^{*}\right)^{\top} A^{\top} A x^{*} \tag{1}
\end{align*}
$$

Hence

$$
\left(x^{*}\right)^{\top} A^{\top} b=\left(x^{*}\right)^{\top} A^{\top} A x^{*}=\left\|A x^{*}\right\|_{2}^{2} \leq\|b\|_{2}^{2} .
$$

Moreover because $M \leq \lambda A^{\top} A$,

$$
\left\|x^{(0)}-x^{*}\right\|_{M}^{2}=b^{\top} A M A^{\top} b \leq \lambda b^{\top} A A^{\top} A A^{\top} b=\lambda\left\|A A^{\top} b\right\|_{2}^{2}
$$

Therefore by Lemma 9

$$
\begin{equation*}
\left\|x^{(k)}-x^{*}\right\|_{M} \leq\left(1-\frac{1}{\lambda}\right)^{k}\left\|x^{(0)}-x^{*}\right\|_{M} \leq\left(1-\frac{1}{\lambda}\right)^{k} \lambda\left\|A A^{\top} b\right\|_{2}^{2} \tag{2}
\end{equation*}
$$

Moreover

$$
\begin{aligned}
\left\|A x^{(k)}-b\right\|_{2}^{2} & =\left(A x^{(k)}-b\right)^{\top}\left(A x^{(k)}-b\right)=\left(x^{(k)}\right)^{\top} A^{\top} A x^{(k)}+b^{\top} b-2\left(x^{(k)}\right)^{\top} A^{\top} b \\
& =\left(x^{(k)}\right)^{\top} A^{\top} A x^{(k)}+b^{\top} b-2\left(x^{(k)}\right)^{\top} A^{\top} A x^{*} .
\end{aligned}
$$

Therefore if $\left\|x^{(k)}-x^{*}\right\|_{M}^{2} \leq \epsilon\left\|A x^{*}-b\right\|_{2}^{2}$, because $A^{\top} A \leq M$, then

$$
\left(x^{(k)}-x^{*}\right)^{\top} A^{\top} A\left(x^{(k)}-x^{*}\right) \leq\left\|x^{(k)}-x^{*}\right\|_{M}^{2} \leq \epsilon\left\|A x^{*}-b\right\|_{2}^{2}
$$

Hence by (1),

$$
\left(x^{(k)}\right)^{\top} A^{\top} A x^{(k)}-2\left(x^{(k)}\right)^{\top} A^{\top} A x^{*}+\left(x^{*}\right)^{\top} A^{\top} A x^{*} \leq \epsilon\left(b^{\top} b-\left(x^{*}\right)^{\top} A^{\top} A x^{*}\right)
$$

Thus

$$
\left(x^{(k)}\right)^{\top} A^{\top} A x^{(k)}-2\left(x^{(k)}\right)^{\top} A^{\top} A x^{*}+b^{\top} b \leq(1+\epsilon)\left(b^{\top} b-\left(x^{*}\right)^{\top} A^{\top} A x^{*}\right)
$$

Therefore by $A^{\top} b=A^{\top} A x^{*}$,

$$
\left\|A x^{(k)}-b\right\|_{2}^{2} \leq(1+\epsilon)\left\|A x^{*}-b\right\|_{2}^{2}
$$

Thus it is enough to set the number of iterations to $k \geq \lambda \log \left(\frac{\lambda\left\|A A^{\top} b\right\|_{2}^{2}}{\epsilon\left\|A x^{*}-b\right\|_{2}^{2}}\right)$. Moreover note that each iteration of the algorithm takes $\tilde{O}\left(n n z(A)+n n z_{d}(A) \cdot m+d^{2}\right)$ time. The other terms of the running time come from Theorem 8 to find a spectral approximation. Therefore the total running time of the algorithm is

$$
\tilde{O}\left(\left(n n z(A)+d \cdot n n z_{d}(A) \cdot m+d^{2} \cdot m^{3}+\left(\frac{d}{m}\right)^{\omega} m^{2}\right) \cdot \log ^{2}(\kappa) \log \left(\frac{\lambda\left\|A A^{\top} b\right\|_{2}^{2}}{\epsilon\left\|A x^{*}-b\right\|_{2}^{2}}\right)\right)
$$

The result follows by picking $m=\min \left\{d \cdot n n z_{d}(A)^{\frac{1}{\omega-1}}, d^{\frac{\omega-2}{\omega+1}}\right\}$.

### 3.3 Tall p-Norm Regression

Bubeck et al [6] introduced the following quadratically smoothed p-norm function.
Definition 5. Let $\gamma: \mathbb{R}_{\geq} \times \mathbb{R} \rightarrow \mathbb{R}$, where

$$
\gamma(t, x)= \begin{cases}\frac{p}{2} t^{p-2} x^{2} & \text { if }|x| \leq t \\ |x|^{p}+\left(\frac{p}{2}-1\right) t^{p} & \text { otherwise }\end{cases}
$$

Slightly abusing the notation, for $x, t \in \mathbb{R}^{n}$, we define $\gamma(t, x):=\left(\gamma\left(t_{1}, x_{1}\right), \ldots, \gamma\left(t_{n}, x_{n}\right)\right)$.
Lemma 14. The function $\gamma$ has the following properties.

1. $\gamma(0, x)=|x|^{p}$.
2. $\gamma(t, \cdot)$ is quadratic on $[-t, t]$;
3. $\gamma$ is in $C^{1}$.

Using this function, [6] developed a homotopy based algorithm for solving the p-norm regression problem - see Algorithm 2 The algorithm starts with a large $t$ and decreases $t$ over a logarithmic number of phases. The reason that this algorithm works is that the following "quadratic extension" is well-conditioned on a box $(l \leq x \leq u)$ around the optimal solution of $t_{k}$ which includes the optimal solution for $t_{k+1}$.

## Definition 6.

$$
f_{t, \ell, u}(s)= \begin{cases}\gamma(t, s) & \text { if } \ell \leq s \leq u \\ \gamma(t, u)+\frac{d}{d s} \gamma(t, u) \cdot(s-u)+\frac{1}{2} \frac{d^{2}}{\frac{d s^{2}}{2}} \gamma(t, u) \cdot(s-u)^{2} & \text { if } u \leq s \\ \gamma(t, \ell)+\frac{d}{d s} \gamma(t, \ell) \cdot(s-\ell)+\frac{1}{2} \frac{d^{2}}{d s^{2}} \gamma(t, \ell) \cdot(s-\ell)^{2} & \text { if } s \leq \ell\end{cases}
$$

Now we are equipped to give a high-level description of the algorithm for tall p-norms.

1. Set $t_{0}=2\|b\|_{2}$ and $x\left(t_{0}\right)=\arg \min _{x}\|A x-b\|_{2}^{2}$.
2. Repeat the following for $k=1, \ldots, O(1) \cdot \log \left(n p t_{0}^{p} / \epsilon\right)$
(a) Set $t_{k}=\left(1-\frac{1}{2 p}\right) t_{k-1}$
(b) Set $x\left(t_{k}\right)=\arg \min _{x} \gamma\left(t_{k}, A x-b\right)$

First of all if $t_{k}$ is small enough, then $x\left(t_{k}\right)$ is close to the optimal solution of min $\|A x-b\|_{p}^{p}$ (see Lemma 5 of [6]). Second, the crux of the above algorithm is to implement Step (b). In general the condition number of $\gamma$ function can be large. Therefore instead of minimizing $\gamma\left(t_{k}, A x-b\right)$ itself, we minimize the quadratic extension $f_{t_{k}, l, u}(A x-b)$ for the appropriate bounds $l$, $u$ (see Definition 6). The functions $\gamma$ and $f_{t, l, u}$ have unique minimizers because of their strict convexity property. Therefore if we pick $l$ and $u$ such that $l \leq A\left(\arg \min _{x} \gamma\left(t_{k}, A x-b\right)\right)-b \leq u$, then finding the minimum of $f_{t_{k}, l, u}(A x-b)$ is equivalent to finding the minimum of $\gamma\left(t_{k}, A x-b\right)$. Moreover the condition number of $f_{t_{k}, l, u}(A x-b)$ is equal to the condition number of $\gamma\left(t_{k}, A x-b\right)$ restricted to the set $\{x: l \leq A x-b \leq u\}$. We pick $l$ and $u$ that determine a neighborhood around $A x\left(t_{k-1}\right)-b$ that contains $A x\left(t_{k}\right)-b$. The algorithm works because $A x\left(t_{k-1}\right)-b$ and $A x\left(t_{k}\right)-b$ are close to each other. Therefore $\left\{x: l \leq A x\left(t_{k-1}\right)-b \leq u\right\}$, that contains $A x\left(t_{k}\right)-b$. is small enough so that $\gamma\left(t_{k}, A x-b\right)$ on this set has a small condition number - see Section 2.2 of [6].

Finally, note that $f_{t_{k}, l, u}$ is well-conditioned with respect to $A x-b$ and not necessarily with respect to $x$. Therefore we need to use a preconditioner $A P^{(k)}$ such that $f_{t_{k}, l, u}\left(A P^{(k)} y-b\right)$ is well-conditioned with respect to $y$. For this we pick $P^{(k)}=\left(\widetilde{A}^{\top} \widetilde{A}\right)^{+} \widetilde{A}^{\top}$ where $\widetilde{A}$ is a constant-factor spectral approximation (with $\tilde{O}(d)$ rows) of $\sqrt{D^{(k)}} A$ and $D^{(k)}$ is a diagonal matrix such that $D_{i i}^{(k)}=\frac{p-1}{2} \max \left\{t_{k}^{p / 2},\left|\left(A x^{(k)}-b\right)_{i}\right|^{p / 2}-\operatorname{sign}(p-2) \gamma\right\}^{2-4 / p}$ - see Sections 2.2 and 3 of [6] for details. To find the spectral approximation, we use Theorem 8 and to find the inverse of $\widetilde{A}^{\top} \widetilde{A}$, we use the sparse linear system solver (Theorem 7 ).

In summary, 6] proves the following result.
Theorem 15 ([6]). Algorithm 2 returns $\bar{x}$ such that

$$
\|A \bar{x}-b\|_{p}^{p} \leq \epsilon+\min _{x \in \mathbb{R}^{d}}\|A x-b\|_{p}^{p},
$$

```
Algorithm 2: Tall \(p\)-norm regression
    Input: \(A \in \mathbb{R}^{n \times d}, b \in \mathbb{R}^{n}, p \in(1, \infty), \epsilon>0\)
    \(t_{0} \leftarrow 2\|b\|_{2}, \gamma \leftarrow\left(1+\frac{p^{2}}{2(p-1)} \sqrt{n}\right) t^{p / 2}\)
    Find a 2-spectral approximation \(\widetilde{A}\) of \(A\) and set \(x^{(0)}=\arg \min _{x}\|A x-b\|_{2}^{2} ; / /\) The solution to
    this regression problem is found using Theorem 2, i.e., Richardson's iterations
    that use \(2 \widetilde{A}^{\top} \widetilde{A}\) as the preconditioner.
    \(z \leftarrow O(1) \cdot \log \left(n p t_{0}^{p} / \epsilon\right)\)
    forall \(k=0,1, \ldots z\) do
        \(t_{k+1} \leftarrow\left(1-\frac{1}{2 p}\right) t_{k}\)
        Set \(D^{(k)}\) to a diagonal matrix where \(D_{i i}^{(k)}=\frac{p-1}{2} \max \left\{t_{k}^{p / 2},\left|\left(A x^{(k)}-b\right)_{i}\right|^{p / 2}-\operatorname{sign}(p-2) \gamma\right\}^{2-4 / p}\)
        Find a constant-factor spectral approximation \(\widetilde{A^{(k)}}\), with \(\tilde{O}(d)\) rows of \(\sqrt{D^{(k)}} A\).
        \(P^{(k)} \leftarrow\left(\left(\widetilde{A}^{(k)}\right)^{\top} \widetilde{A}^{(k)}\right)^{+}\left(\widetilde{A}^{(k)}\right)^{\top} ; \quad / /\) Use the sparse linear system solver (Theorem 7)
        to find the inverse.
        Given \(x^{(k)}, P^{(k)}\), find \(y^{(k+1)}\) by minimizing the following function using mini-batch Katyusha 3 ]
            on
\[
\begin{equation*}
g^{(k)}(y):=\sum_{i=1}^{n} f_{t_{k+1},\left(\left|\left(A x^{(k)}-b\right)_{i}\right|^{p / 2}-\gamma\right)^{2 / p},\left(\left|\left(A x^{(k)}-b\right)_{i}\right|^{p / 2}+\gamma\right)^{2 / p}\left(\left(A P^{(k)} y-b\right)_{i}\right), ~, ~ . ~}^{\text {. }} \tag{3}
\end{equation*}
\]
For each iteration of mini-batch Katyusha, we compute the following, for a set \(S \subseteq[n]\) of size \(\eta\),
\[
\sum_{i \in S} \nabla F_{i}(x)=P^{(k)} \sum_{i \in S} f_{(1-h) t_{k},\left(\left|s_{i}(t)\right|^{p / 2}-\gamma\right)^{2 / p},\left(\left|s_{i}(t)\right|^{p / 2}+\gamma\right)^{2 / p}}^{\prime}\left(a_{i} \cdot P^{(k)} y-b_{i}\right) a_{i}
\]
Compute \(x^{(k+1)}\) by the formula \(x^{(k+1)} \leftarrow P^{(k)} y^{(k+1)}\).
return \(x^{(z)}\)
```

We show that, using the sparse inverse solver to find the initial solution and preconditioners in this algorithm improves the running time of the algorithm to better than $d^{\omega}$.

Theorem 4. [Sparse $p$-norm, $p$ near 2] Let $A \in \mathbb{R}^{n \times d}$, where $n \geq d$, be a matrix with condition number $\kappa$. Let $x^{*}=\arg \min \|A x-b\|_{p}^{p}$. There is an algorithm that finds $\bar{x}$ such that

$$
\|A \bar{x}-b\|_{p}^{p} \leq(1+\epsilon)\left\|A x^{*}-b\right\|_{p}^{p}
$$

in time

$$
\tilde{O}\left(\left(n n z(A)+d^{0.5 \max \left\{p, \frac{p}{p-1}\right\}+1}+n n z_{d}(A)^{\frac{\omega-2}{\omega-1}} d^{2}+d^{\frac{5 \omega-4}{\omega+1}}\right) \log ^{2}(\kappa / \epsilon) \log \left(\frac{\kappa\|b\|_{2}}{\epsilon O P T}\right)\right),
$$

with probability at least $1-\tilde{O}\left(d^{-10}\right)$.
Proof. In this proof, for brevity, we show the running time of the sparse linear system solver with $d^{\theta}$. We show that Algorithm 2 runs in the mentioned time complexity. First note that, by Lemma 9 and Theorem 8, we can compute $x^{(0)}$ in time $\tilde{O}\left(n n z(A)+d^{\theta}\right)$. Moreover, $D^{(k)}$ can be computed in $O_{p}(n)$ because it is a diagonal matrix.

We can find this spectral approximation by Theorem 8 in time $\tilde{O}\left(n n z(A)+d^{\theta}\right)$. Note that to multiply a vector $y$ with $P^{(k)}$ we need to first multiply by $\left(\widetilde{A}^{(k)}\right)^{\top}$, which takes $\tilde{O}\left(n n z_{d}(A)\right)$ because $\widetilde{A}^{(k)}$ contains $\tilde{O}(d)$ (scaled) rows of $\sqrt{D^{(k)}} A$. We then have to multiply $\left(\widetilde{A}^{(k)}\right)^{\top} y$ with $\left(\left(\widetilde{A}^{(k)}\right)^{\top} \widetilde{A}{ }^{(k)}\right)^{+}$. By Theorem 7. this process takes $\tilde{O}\left(n n z_{d}(A) \cdot m+d^{2}\right)$ time. Then for a set $S \subseteq[n]$ of size $\eta, \sum_{i \in S} \nabla F_{i}(x)$ can be computed in time $O\left(n n z(A) \frac{\eta}{n}\right)$ after computing $P^{(k)} y$. Therefore each iteration of mini-batch Katyusha takes $O\left(n n z(A) \frac{\eta}{n}+n n z_{d}(A) \cdot m+d^{2}\right)$ in expectation. Note that $n n z_{d}(A) \cdot m \leq d^{2}$ by assumption. Moreover in each phase of the algorithm, we pay a preprocessing time of $O\left(n n z(A)+d^{\theta}\right)$ to find the linear operator for $P^{(k)}$, i.e, the inverse operator of $\left(\widetilde{A}^{(k)}\right)^{\top} \widetilde{A}^{(k)}$. Moreover as discussed in [6] the smoothness and strong convexity parameters of the function are equal to $L=O_{p}\left(n^{|1-2 / p|}\right)$ and $\sigma=\Omega(1)$, respectively. Also the sum of smoothness parameters of $F_{i}$ functions is equal to $\sum_{i \in[n]} L_{i}=O_{p}\left(n^{|1-2 / p|} d\right)$. Let $\kappa=L / \sigma$ be the condition number of the Hessian. Then mini-batch Katyusha takes $\tilde{O}_{p}\left(\frac{n}{\eta}+\sqrt{\kappa}+\frac{1}{\eta} \sqrt{n \kappa d}\right)$ iterations. Let $Z=n n z(A)$. Then the total running time of the algorithm is

$$
\begin{aligned}
& \tilde{O}_{p}\left[\left(\frac{n}{\eta}+\sqrt{\kappa}+\frac{1}{\eta} \sqrt{n \kappa d}\right)\left(Z \frac{\eta}{n}+d^{2}\right)+Z+d^{\theta}\right] \\
& =\tilde{O}_{p}\left[Z\left(1+\sqrt{\frac{\kappa d}{n}}\right)+d^{\theta}+d^{2} \sqrt{\kappa}+\frac{d^{2} \sqrt{n}}{\eta}(\sqrt{\kappa d}+\sqrt{n})+Z \sqrt{\kappa} \frac{\eta}{n}\right]
\end{aligned}
$$

We now optimize $\eta$ over $\frac{d^{2} \sqrt{n}}{\eta}(\sqrt{\kappa d}+\sqrt{n})+Z \sqrt{\kappa} \frac{\eta}{n}$. If $\kappa d \geq n$, then we choose $\eta=\left\lceil\sqrt{\frac{n^{3 / 2} d^{5 / 2}}{Z}}\right\rceil$. Then

$$
\frac{d^{2} \sqrt{n}}{\eta}(\sqrt{\kappa d}+\sqrt{n})+Z \sqrt{\kappa} \frac{\eta}{n}=O\left(\sqrt{Z} d^{5 / 4} n^{-1 / 4} \sqrt{\kappa}\right) \leq O\left(Z \sqrt{\frac{\kappa d}{n}}+d^{2} \sqrt{\kappa}\right)
$$

where the inequality follows from the AM-GM inequality. Therefore the total cost is

$$
\tilde{O}_{p}\left[Z\left(1+\sqrt{\frac{\kappa d}{n}}\right)+d^{\theta}+d^{2} \sqrt{\kappa}\right]
$$

Because $\kappa \leq O\left(n^{|1-2 / p|}\right)$, $\kappa d \geq n$ implies $n \leq O_{p}\left(d^{p / 2}\right)$ if $p \geq 2$, and $n \leq O_{p}\left(d^{\frac{1}{2-2 / p}}\right)$ if $p \leq 2$. Therefore for $p \geq 2$, we have

$$
\begin{aligned}
\tilde{O}_{p}\left[Z\left(1+\sqrt{\frac{\kappa d}{n}}\right)+d^{\theta}+d^{2} \sqrt{\kappa}\right] & =\tilde{O}_{p}\left[Z+n d \sqrt{\frac{\kappa d}{n}}+d^{\theta}+n^{1 / 2-1 / p} d^{2}\right] \\
& \leq \tilde{O}_{p}\left[Z+d^{p / 2+1}+d^{\theta}+n+\left(d^{2}\right)^{\frac{1}{1 / 2+1 / p}}\right] \\
& =\tilde{O}_{p}\left[Z+d^{p / 2+1}+d^{\theta}+n+d^{\frac{4}{1+2 / p}}\right]
\end{aligned}
$$

$$
=\tilde{O}_{p}\left[Z+n+d^{p / 2+1}+d^{\theta}\right]
$$

where the first inequality follows from the weighted AM-GM. The second inequality follows from $\frac{4}{1+2 / p} \leq \frac{p}{2}+1$. For $p \leq 2$, similarly, we can show that

$$
\tilde{O}_{p}\left[Z\left(1+\sqrt{\frac{\kappa d}{n}}\right)+d^{\theta}+d^{2} \sqrt{\kappa}\right]=\tilde{O}_{p}\left[Z+n+d^{\theta}+d^{\frac{p}{2(p-1)}+1}\right]
$$

If $\kappa d \leq n$, then we choose $\eta=\left\lceil\sqrt{\frac{n^{2} d^{2}}{Z \sqrt{\kappa}}}\right\rceil$ and then

$$
\frac{d^{2} \sqrt{n}}{\eta}(\sqrt{\kappa d}+\sqrt{n})+Z \sqrt{\kappa} \frac{\eta}{n}=O\left(\sqrt{Z} d \kappa^{1 / 4}\right) \leq O\left(Z+d^{2} \sqrt{\kappa}\right)
$$

Therefore the cost is

$$
\tilde{O}_{p}\left[Z\left(1+\sqrt{\frac{\kappa d}{n}}\right)+d^{\theta}+d^{2} \sqrt{\kappa}\right]=\tilde{O}_{p}\left(Z+d^{\theta}+n+d^{\frac{4}{1+2 / p}}\right) \leq \tilde{O}_{p}\left(Z+d^{\theta}+n+d^{\frac{p}{2}+1}\right)
$$

where the last inequality follows from $\frac{4}{1+2 / p} \leq \frac{p}{2}+1$.
Therefore the total running time of the algorithm is

$$
\tilde{O}\left(\left(n n z(A)+d^{0.5 \max \left\{p, \frac{p}{p-1}\right\}+1}+d \cdot n n z_{d}(A) \cdot m+d^{2} \cdot m^{3}+\left(\frac{d}{m}\right)^{\omega} m^{2}\right) \log ^{2}(\kappa / \epsilon) \log \left(\frac{\kappa\|b\|_{2}}{\epsilon O P T}\right)\right)
$$

The result follows by picking $m=\min \left\{d \cdot n n z_{d}(A)^{\frac{1}{\omega-1}}, d^{\frac{\omega-2}{\omega+1}}\right\}$.

## 4 p-Norm Regression

Adil et al [1] showed that for numbers $x, \Delta \in \mathbb{R}$,

$$
|x|^{p}+\Delta \frac{d}{d x}|x|^{p}+\frac{p-1}{p^{2^{p}}} \gamma(|x|, \Delta) \leq|x+\Delta|^{p} \leq|x|^{p}+\Delta \frac{d}{d x}|x|^{p}+2^{p} \gamma(|x|, \Delta)
$$

where $\gamma$ is the quadratically smoothed $p$-norm function - see Definition 5. Note that both $2^{p}$ and $\frac{p-1}{p^{p}}$ are $O_{p}(1)$. This inequality suggests the following iterative scheme for $p$-norm regression problem.

1. Start from an initial point $x \in \mathbb{R}^{d}$ such that $A x=b$.
2. Repeat the following
(a) Find $\Delta \in \mathbb{R}^{d}$ such that $A \Delta=0$ and minimizes

$$
\begin{equation*}
\sum_{j=1}^{d} \Delta_{j} \frac{d}{d x_{j}}\left|x_{j}\right|^{p}+O_{p}(1) \gamma\left(\left|x_{j}\right|, \Delta_{j}\right) \tag{4}
\end{equation*}
$$

(b) Update $x$ to $x+\Delta$

It is shown that by a logarithmic number of iterations of the above algorithm, one can solve the $p$-norm regression problem to $\epsilon$ accuracy. Moreover, instead of iteration (a) in the above algorithm, we can guess the value of $z=\Delta^{\top} \nabla\|x\|_{p}^{p}$ (in a binary search fashion) and solve a logarithmic number of problems of the following form

$$
\begin{array}{r}
\min _{\Delta} \gamma(x, \Delta)  \tag{5}\\
A \Delta=0
\end{array}
$$

$$
g^{\top} \Delta=z
$$

where $g$ is the gradient vector, $\nabla\|x\|_{p}^{p}$, and we overload the notation for $\gamma$ to denote $\sum_{j=1}^{d} \gamma\left(x_{j}, \Delta_{j}\right)$ with $\gamma(x, \Delta)$. Note that by doing line search on the value of $\Delta^{\top} \nabla\|x\|_{p}^{p}$, we can also remove the $O_{p}(1)$ term completely. Adil et al [1] has shown that it is enough to solve $O_{p}\left(\alpha \log \left(\frac{d}{\epsilon}\right)\right)$ many problems of form (5) to $\alpha$ approximation to solve the $p$-norm regression problem. Theorem 5.8 of [1] states that 5 can be solved by solving $\tilde{O}_{p}\left(d^{\frac{p-2}{3 p-2}}\right)$ many problems of the form

$$
\begin{gather*}
\min _{\Delta} \frac{1}{2} \Delta^{\top} R \Delta  \tag{6}\\
A \Delta=0 \\
g^{\top} \Delta=z
\end{gather*}
$$

where $R$ is a diagonal matrix. Note that (6) is a weighted linear regression problem. To solve (5) using instances of (6), one starts from an initial $R$ and then repeats the following.

1. Solve (6) with $R$ to find $\Delta^{*}$.
2. Update $R$ based on $\Delta^{*}$ via a multiplicative weights update algorithm.

Therefore by the above discussion, one can solve the $p$-norm regression problem by solving $\tilde{O}_{p}\left(\alpha d^{\frac{p-2}{3 p-2}} \log \left(\frac{d}{\epsilon}\right)\right)$ many instances of (6) - see [1]. One caveat of this result is that the number of problems needed to be solved is exponential in $p$. However, this is improved by Adil and Sachdeva [2] to $O\left(p \alpha d^{\frac{p-2}{3 p-2}} \log ^{2}(d / \epsilon)\right)$ solves of instances of (6). This is achieved by showing that a smoothed $p$-norm problem can be solved by solving $p d^{\max \left\{\frac{1}{q}, \frac{1}{p-1}\right\}} \log ^{2}(d / \epsilon)$ instances of the smoothed $q$-norm problem and using a homotopy approach to solve the problem for the following norms $2^{-k} p, 2^{-k+1} p, \ldots, \frac{p}{2}, p$. The $q$ is then picked to be $\sqrt{\log (d)}$ which adds a factor of $d^{o(1)}$ to the running time. The overall result can be summarized as the following.

Theorem 16 ([1, 2]). The problem of

$$
\min _{A x=b}\|x\|_{p}^{p}
$$

can be solved by solving $O\left(p \alpha \log ^{2}\left(\frac{d}{\epsilon}\right)\right)$ instances of the following residual problem each to an $\alpha$ approximation, where the objective value of the optimal solution is less than or equal to one and $d^{-1 / p} \leq t_{j} \leq 1, \forall j$.

$$
\begin{array}{r}
\min _{\Delta} \gamma(t, \Delta) \\
A \Delta=0 \\
g^{\top} \Delta=z
\end{array}
$$

Therefore, we can focus on solving the residual problems of the form (5) by solving instances of (6). First, it is easy to analytically find the solution of the weighted regression problem by the method of Lagrange multipliers.

Theorem 17 ([1]). The solution to the problem

$$
\begin{array}{r}
\min _{\Delta} \frac{1}{2} \Delta^{\top} R \Delta \\
A \Delta=0 \\
g^{\top} \Delta=z
\end{array}
$$

is

$$
\begin{equation*}
\Delta=\frac{z\left(A^{\top} R^{-1} A\right)^{-1} A^{\top} R^{-1} g}{g^{\top} R^{-1} g-g^{\top} R^{-1} A\left(A^{\top} R^{-1} A\right)^{-1} A^{\top} R^{-1} g} \tag{7}
\end{equation*}
$$

Note that to find the vector $\left(A^{\top} R^{-1} A\right)^{-1} A^{\top} R^{-1} g$, we can use a $\tilde{O}(1)$ spectral approximation of $\left(A^{\top} R^{-1} A\right)^{-1}$ and use Richardson's iteration (Lemma 9) to find $\left(A^{\top} R^{-1} A\right)^{-1} A^{\top} R^{-1} g$ with high accuracy in $\tilde{O}(1)$ iterations. Moreover if $\widetilde{R}$ is within an $\tilde{O}(1)$ factor of $R$, then $\left(A^{\top} \widetilde{R}^{-1} A\right)$ is a $\tilde{O}(1)$ spectral approximation of $\left(A^{\top} R^{-1} A\right)$. Therefore it is enough to maintain the inverse $\left(A^{\top} \widetilde{R}^{-1} A\right)^{-1}$ such that $\widetilde{R}$ is within an $\tilde{O}(1)$ factor of $R$ and apply this inverse in the Richardson's iteration to the vector $A^{\top} R^{-1} g$. The reason that this gives improvements is that the entries of $R$ change slowly. Therefore, we can use the following identity to perform the low-rank updates.

Lemma 18 (Sherman-Morrison-Woodbury identity). For an invertible $n \times n$ matrix $M$ and matrices $U \in$ $\mathbb{R}^{n \times r}, C \in \mathbb{R}^{r \times r}, V \in \mathbb{R}^{r \times n}$, we have

$$
(M+U C V)^{-1}=M^{-1}-M^{-1} U\left(C^{-1}+V M^{-1} U\right)^{-1} V M^{-1}
$$

After finding the vector $\left(A^{\top} R^{-1} A\right)^{-1} A^{\top} R^{-1} g$, we can multiply it by $z$ or $g^{\top} R^{-1} A$ to find the terms we need for (7).

Now, we are equipped to state the algorithm for solving the residual problem of the form (5). Note that as we mentioned, we only need to solve about $d^{(p-2) /(3 p-2)}$ instances of weighted linear regression (6) to solve (5). If we naively find the inverse of $A^{\top} R^{-1} A$ for each instance separately, the cost becomes about $d^{\omega+(p-2) /(3 p-2)}$ which is too high. Because the entries of the diagonal matrix $R$ change slowly, we can use the inverse maintenance technique that uses the Sherman-Morrison-Woodbury identity to perform low-rank updates to the inverse in order to maintain a spectral approximation of the true inverse. This spectral approximation can then be used as a preconditioner in the Richardson's iteration (Lemma 9) to compute (7).

There are two important differences between our approach to inverse maintenance and the previous one used by Adil et al [1].

1. We cannot update the inverse matrix directly because we only have access to it via a linear operator - see Section 5 Therefore we keep a dense matrix $Q$ in which the result of low-rank updates is accumulated. Hence our spectral approximation of the inverse is of the form $Y+Q$ where $Y$ is a linear operator for the inverse of $A^{\top}\left(\hat{R}^{(0)}\right)^{-1} A$ computed by the sparse inverse solver of Peng and Vempala [25]. Note that because $Q$ is the result of multiplication of different parts of $Y$, each of its entries have $\tilde{O}(1)$ bits.
2. Because of the cost of access to the inverse operator (see Theorem 7, we cannot allow updates of rank more than about $(d / m)$ where $m$ is the number of blocks of the block Krylov space used for the sparse inverse. Therefore, once every $(d / m)^{(p-2) /(3 p-2)}$ iterations, we compute the sparse inverse from scratch.

Algorithm 3 illustrates the pseudocode of our process. The red lines show the main differences between our algorithm and Adil et al [1]. The next theorem states that Algorithm 3 solves the residual problem and gives a bound on the size of low-rank updates which we use to bound the running time of the algorithm.

Theorem 19 (1]). Suppose for problem (5), the objective of the optimal solution is less than one and $d^{-1 / p} \leq t_{j} \leq 1, \forall j$, then Algorithm 3 returns a solution $\bar{\Delta}$ with high probability such that $A \bar{\Delta}=0, g^{\top} \Delta=z$, and $\gamma(t, \bar{\Delta})$ is within an $O_{p}(1)$ factor of the optimal objective value.

Moreover, let $k_{i, \eta}$ be the number of indices $j$ that are added to $E$ at iteration $i$ due to changes between $2^{-\eta}$ and $2^{-\eta+1}$. Let $t=\tilde{\Theta}_{p}\left(d^{\frac{p-2}{3 p-2}}\right)$ be the number of iterations. Then

$$
\sum_{i=1}^{t} k_{i, \eta}= \begin{cases}0 & \text { if } 2^{\eta}>t  \tag{8}\\ \tilde{O}_{p}\left(d^{\frac{p+2}{3 p-2}} 2^{2 \eta}\right) & \text { otherwise }\end{cases}
$$

The above theorem states that after $k$ iterations of the algorithm at most about $k^{3}$ of the weights have changed significantly. Now, we are equipped to bound the time complexity of solving the residual problem (5).

```
Algorithm 3: Algorithm for the Residual Problem - Steps (1) and (5), underlined, are new.
    Input: \(A \in \mathbb{R}^{n \times d}, t \in \mathbb{R}^{d}, g \in \mathbb{R}^{d}, z \in \mathbb{R}, p \in(1, \infty)\)
    \(w_{j}^{(0)} \leftarrow 0, \forall j \in[d]\)
    \(3 x \leftarrow \overrightarrow{0}\)
    \(4 \rho \leftarrow \tilde{\Theta}_{p}\left(d^{\frac{\left(p^{2}-4 p+2\right)}{p(3 p-2)}}\right)\)
    \(5 \beta \leftarrow \tilde{\Theta}_{p}\left(d^{\frac{p-2}{3 p-2}}\right)\)
    \(6 \alpha \leftarrow \tilde{\Theta}_{p}\left(d^{-\frac{\left(p^{2}-5 p+2\right)}{p(3 p-2)}}\right)\)
    \(7 \tau \leftarrow \tilde{\Theta}_{p}\left(d^{\frac{(p-1)(p-2)}{(3 p-2)}}\right)\)
    \(8 t=\alpha^{-1} d^{1 / p}=\tilde{\Theta}_{p}\left(d^{\frac{p-2}{3 p-2}}\right)\)
    \(9 r_{j}^{(0)} \leftarrow\left(d^{1 / p} t_{j}\right)^{p-2}, \forall j \in[d]\)
    forall \(i=0, \ldots, t\) do
        (1) Recompute the sparse inverse operator.
        if \(i\) is a multiple of \((d / m)^{(p-2) /(3 p-2)}\) then
            \(\hat{r}_{j} \leftarrow r_{j}^{(i)}, \forall j \in[d]\)
            \(\overline{c_{j, \eta} \leftarrow 0 \text { for all } j} \in[d]\) and \(\eta \in[\log (t)] \cup\{0\}\)
            Use Theorem 7 to find inverse operator for \(A^{\top} \hat{R}^{-1} A\) with error \(\kappa^{-10} d^{-10}, Y\).
            Set \(Q\) to a \(d \times d\) matrix of all zeros.
            (2) Solve the weighted linear regression by Richardson's iteration and
            preconditioning. See Section 3.1, Lemma 9, and Theorem 2,
            \(\Delta^{*}=\arg \min _{\Delta} \sum_{j \in[d]} r_{j} \Delta_{j}^{2}\) s.t. \(A \Delta=0\) and \(g^{\top} \Delta=z\). // The solution is given by (7) and
            we can use \(Y+Q\) as a preconditioner to find \(\Delta^{*}\) with a high accuracy.
            (3) Update the weights.
            if \(\left\|\Delta^{*}\right\|_{p}^{p} \leq \tau\) then
            \(w_{j}^{(i+1)} \leftarrow w_{j}^{(i)}+\alpha\left|\Delta_{j}^{*}\right|, \forall j \in[d]\)
            \(x \leftarrow x+\alpha \Delta^{*}\)
        else
            For all \(j \in[d]\) with \(\left|\Delta_{j}\right| \geq \rho\) and \(r_{j} \leq \beta\) do
                    \(w_{j}^{(i+1)} \leftarrow 4^{1 /(p-2)} \max \left\{d^{1 / p}, w_{j}^{(i)}\right\}\)
            For rest of \(j \in[d]\) do \(w_{j}^{(i+1)} \leftarrow w_{j}^{(i)}\)
        \(r_{j}^{(i+1)} \leftarrow\left(d^{1 / p} t_{j}\right)^{p-2}+w_{j}^{p-2}\)
        (4) Find the significant buckets.
        For all \(j \in[d]\) find the least non-negative integer \(\eta_{j}\) such that \(\frac{1}{2^{\eta_{j}}} \leq \frac{r_{j}^{(i+1)}-r_{j}^{(i)}}{\hat{r}_{j}}\)
        For all \(j \in[d], c_{j, \eta_{j}} \leftarrow c_{j, \eta_{j}}+1\)
        \(E \leftarrow \cup_{\eta: i+1} \bmod 2^{\eta} \equiv 0\left\{j: c_{j, \eta} \geq 2^{\eta}\right\}\)
        \(\hat{r}_{j} \leftarrow r_{j}^{(i+1)}, \forall j \in E\)
        \(c_{j, \eta} \leftarrow 0\) for all \((j, \eta)\) such that \(j \in E\).
        (5) Update the preconditioner.
        \(Q \leftarrow Q-(Y+Q)\left(A_{E}\right)^{\top}\left(\left(R^{(i+1)}\right)_{E, E}^{-1}+A_{E}(Y+Q)\left(A_{E}\right)^{\top}\right)^{-1} A_{E}(Y+Q)\).
    return \(d^{-1 / p_{x}}\)
```

Theorem 6. [Sparse general p-norm] Let $2<p<\infty$. Let $A \in \mathbb{R}^{n \times d}$, where $n \leq d$, be a matrix with condition number к. Let $x^{*}=\arg \min _{A x=b}\|x\|_{p}^{p}$. Let $m<d^{1 / 4}$ be the number of blocks in the block Krylov matrix used
by the sparse linear system solver. There is an algorithm that finds $\bar{x}$ such that $A \bar{x}=b$ and

$$
\|\bar{x}\|_{p}^{p} \leq(1+\epsilon)\left\|x^{*}\right\|_{p}^{p}
$$

in time
$\tilde{O}\left(\left(n n z(A) \cdot d \cdot m^{\frac{(p+2)}{(3 p-2)}}+d^{2} \cdot m^{3+\frac{(p-2)}{(3 p-2)}}+d^{2+\frac{p-(10-4 \omega)}{3 p-2}}+d^{\omega} m^{2+\frac{(p-2)}{(3 p-2)}-\omega}\right) d^{o(1)}(p \log p) \log ^{2}(\kappa / \epsilon) \log \left(\frac{\kappa\|b\|_{2}}{\epsilon O P T}\right)\right)$
with probability at least $1-\tilde{O}\left(d^{-10}\right)$.
Proof. First, note that the only randomness of the algorithm comes from finding the inverse matrices in iterations that are multiples of $(d / m)^{(p-2) /(3 p-2)}$. Because the number of iterations of the algorithm is $\tilde{O}_{p}\left(d^{(p-2) /(3 p-2)}\right)$, using the sparse inverse approach of [25], i.e, Theorem 16, the algorithm succeeds with high probability.

Next, we need to bound the time complexity of Algorithm 3. Note that the time complexity of this algorithm is bounded by finding the sparse inverse operators (Line 14), solving the weighted linear regression problems (Line 16), and performing low-rank updates to the inverse (Line 29). In the following, we bound the running time of these.

Running time of finding the sparse inverse operators. The algorithm has at most $\tilde{O}_{p}\left(d^{(p-2) /(3 p-2)}\right)$ iterations and we compute the sparse inverse once every $\tilde{O}_{p}\left((d / m)^{(p-2) /(3 p-2)}\right)$ iterations. Therefore, by Theorem 7, the total cost of computing sparse inverse operators over the course of the algorithm is

$$
\tilde{O}_{p}\left(m^{(p-2) /(3 p-2)}\left(d \cdot n n z(A) \cdot m+d^{2} \cdot m^{3}+d^{\omega} m^{2-\omega}\right)\right)
$$

Running time of solving weighted linear regression problems using the preconditioner $Y+Q$. As discussed in the beginning of this section, to find the solution (7) to the weighted regression problem (6), it is enough to have an inverse $\left(A^{\top} \widetilde{R}^{-1} A\right)^{-1}$, where $\widetilde{R}$ is within a factor of $\tilde{O}(1)$ of $R$, and use this inverse in the Richardson's iteration (Lemma 9). We call $\left(A^{\top} \widetilde{R}^{-1} A\right)^{-1}$ a preconditioner for $\left(A^{\top} R^{-1} A\right)^{-1}$. Note that $Y+Q$ (see Algorithm 3), provides such a preconditioner. The reason is that the algorithm checks once every $2^{\eta}$ iterations whether the number of changes of size between $2^{-\eta}$ and $2^{-\eta+1}$ to an entry is more than $2^{\eta}$. This way the algorithm guarantees the contribution of such changes to an entry is at most $2^{-\eta+1} \cdot 2^{\eta} \cdot 2=4$. Moreover there are a logarithmic number of different $\eta$ 's. Therefore $\widetilde{R}$ can be at most $\tilde{O}(1)$ far from $R$.

By Theorem 17 and Lemma 9 to solve the weighted linear regression problems, we need to compute $A^{\top} R^{-1} g$ and do a logarithmic number of matrix vector multiplications with the spectral approximation of $\left(A^{\top} R^{-1} A\right)^{-1}$ that is provided by $Y+Q$. Note that computing $A^{\top} R^{-1} g$ takes $O(n n z(A))$ time. By Theorem 7 , the cost of the multiplications is $\tilde{O}\left(d^{2}+n n z(A) \cdot m\right)=\tilde{O}\left(d^{2}\right)$ and by assumption $n n z(A) \cdot m \leq d^{2}$. Therefore because the algorithm has $\tilde{O}_{p}\left(d^{(p-2) /(3 p-2)}\right)$ iterations, the total cost of solving weighted linear regression problems is

$$
\tilde{O}_{p}\left(d^{(p-2) /(3 p-2)} d^{2}\right)
$$

Running time of low rank updates. Because we find the sparse inverse operator once every $(d / m)^{(p-2) /(3 p-2)}$ iterations. No low rank update happens due to $\eta$ that $2^{\eta}>(d / m)^{(p-2) /(3 p-2)}$.

We list the operations and the respective running times needed to do an update of rank $r$ in the following.

1. Computing $(Y+Q)\left(A_{E}\right)^{\top}$. By theorem 7, the cost of multiplying the sparse inverse with a $d \times r$ matrix is $\tilde{O}\left(r \cdot n n z(A) \cdot m+d^{2} r^{\omega-2}\right)$. Moreover, $Q$ is an $d \times d$ matrix such that each entry of which has $\tilde{O}(1)$ bits. Therefore multiplying $Q$ by a $d \times r$ matrix takes

$$
\tilde{O}(\operatorname{MM}(d, d, r)) \leq \tilde{O}\left(\left(\frac{d}{r}\right)^{2} \mathrm{MM}(r, r, r)\right)=\tilde{O}\left(d^{2} r^{\omega-2}\right)
$$

time. Computing $A_{E}(Y+Q)$ is similar.
2. Computing $\left(\left(R^{(i+1)}\right)_{E, E}^{-1}+A_{E}(Y+Q)\left(A_{E}\right)^{\top}\right)^{-1}$. Computing $A_{E}(Y+Q)\left(A_{E}\right)^{\top}$ is a left multiply by $A_{E}$ which has size $r \times d$. This multiplication takes

$$
\tilde{O}(\mathrm{MM}(r, d, r)) \leq \tilde{O}\left(\frac{d}{r} \mathrm{MM}(r, r, r)\right)=\tilde{O}\left(d r^{\omega-1}\right) \leq \tilde{O}\left(d^{2} r^{\omega-2}\right)
$$

time, where the last inequality follows from $r \leq d$. Finally $\left(\left(R^{(i+1)}\right)_{E, E}^{-1}+A_{E}(Y+Q)\left(A_{E}\right)^{\top}\right)$ is an $r \times r$ matrix and each of its entries have $\tilde{O}(1)$ bits. Therefore computing its inverse takes $\tilde{O}\left(r^{\omega}\right) \leq \tilde{O}\left(d^{2} r^{\omega-2}\right)$.
3. Computing $(Y+Q)\left(A_{E}\right)^{\top}\left(\left(R^{(i+1)}\right)_{E, E}^{-1}+A_{E}(Y+Q)\left(A_{E}\right)^{\top}\right)^{-1} A_{E}(Y+Q)$. For this we need to multiply a $d \times r$ matrix with an $r \times r$ matrix and then multiply a $d \times r$ matrix with an $r \times d$ matrix. This takes

$$
\tilde{O}(\operatorname{MM}(d, r, d)+\operatorname{MM}(d, r, r))=\tilde{O}(\mathrm{MM}(d, r, d)) \leq \tilde{O}\left(\left(\frac{d}{r}\right)^{2} \mathrm{MM}(r, r, r)\right)=\tilde{O}\left(d^{2} r^{\omega-2}\right)
$$

time.
Therefore the cost of an update of rank $r$ is $\tilde{O}\left(r \cdot n n z(A) \cdot m+d^{2} r^{\omega-2}\right)$. Hence, by Theorem 19 , the total cost of low rank updates over the course of the algorithm is

$$
\begin{aligned}
& \quad \sum_{\eta=0}^{\log (d / m)^{(p-2) /(3 p-2)}} \sum_{i=0}^{z}\left(k_{i, \eta} \cdot n n z(A) \cdot m+d^{2}\left(k_{i, \eta}\right)^{\omega-2}\right) \\
& =(n n z(A) \cdot m)\left(\sum_{\eta=0}^{\log (d / m)^{(p-2) /(3 p-2)}} \sum_{i=0}^{z} k_{i, \eta}\right)+d^{2} \sum_{\eta=0}^{\log (d / m)^{(p-2) /(3 p-2)}} \sum_{i=0}^{z}\left(k_{i, \eta}\right)^{\omega-2} \\
& \leq \tilde{O}_{p}\left(n n z(A) \cdot m \cdot d^{(p+2) /(3 p-2)} \cdot\left(\frac{d}{m}\right)^{2(p-2) /(3 p-2)}\right)+d^{2} \sum_{\eta=0}^{\log (d / m)} \sum_{p}^{(p-2) /(3 p-2)} \tilde{O}_{p}\left(d^{\frac{p-(10-4 \omega)}{3 p-2}} 2^{\eta(3 \omega-7)}\right) \\
& \leq \tilde{O}_{p}\left(n n z(A) \cdot d \cdot m^{(p+2) /(3 p-2)}\right)+\tilde{O}_{p}\left(d^{2} d^{\frac{p-(10-4 \omega)}{3 p-2}}\left(1+\frac{d^{\frac{(p-2)(3 \omega-7)}{3 p-2}}}{m^{(p-2) /(3 p-2)}}\right)\right) \\
& =\tilde{O}_{p}\left(n n z(A) \cdot d \cdot m^{(p+2) /(3 p-2)}+d^{2+\frac{p-(10-4 \omega)}{3 p-2}}+\frac{d^{\omega}}{m^{(p-2) /(3 p-2)}}\right)
\end{aligned}
$$

where the first inequality follows from Theorem 7 and the concavity of the function $f(a)=a^{\omega-2}$, which implies that the maximum of the summation happens when all the summands are equal. The second inequality follows from the fact that the maximum summand of the summation is either for $\eta=0$ or $\eta=\log (d / m)^{(p-2) /(3 p-2)}$ depending on whether $3 \omega-7$ is positive or negative.

Numerical stability of inverse maintenance. The inverse operator $Y$ that we start with has some error (see Theorem 7). We need to argue that this error does not increase over the iterations where we do inverse maintenance using the Sherman-Morrison-Woodbury identity. Lemma 20 shows that the inverse maintenance using Sherman-Morrison-Woodbury identity is numerically stable. The round-off error of finding the low-rank inverses does not increase the overall error by assuming that the round-off error is much smaller than the error of the sparse inverse solver. For the numerical stability of matrix operations, see [14, 13]. For stability of inverse maintenance (in the context of linear programming), see [26].

Lemma 20 (Numerical stability of inverse maintenance by Sherman-Morrison-Woodbury identity). Let $Z, \widetilde{Z}, C$ be positive semi-definite matrices. Let $0<\epsilon<1$. Suppose

$$
\begin{equation*}
\frac{1}{1+\epsilon} Z^{-1} \leq \widetilde{Z}^{-1} \leq \frac{1}{1-\epsilon} Z^{-1} \tag{9}
\end{equation*}
$$

Then

$$
\frac{1}{1+\epsilon}\left(Z+U^{\top} C U\right)^{-1} \leq \widetilde{Z}^{-1}-\widetilde{Z}^{-1} U\left(C^{-1}+U^{\top} \widetilde{Z}^{-1} U\right)^{-1} U^{\top} \widetilde{Z}^{-1} \leq \frac{1}{1-\epsilon}\left(Z+U^{\top} C U\right)^{-1}
$$

Proof. First note that because $C$ is positive semi-definite $U^{\top} C U$ is also positive semi-definite. Moreover $(1-\epsilon)\left(U^{\top} C U\right) \leq U^{\top} C U \leq(1+\epsilon)\left(U^{\top} C U\right)$. Because $\epsilon<1,(1-\epsilon)\left(U^{\top} C U\right)$ is positive semi-definite. Therefore by assumption (9),

$$
(1-\epsilon)\left(Z+U^{\top} C U\right) \leq\left(\widetilde{Z}+U^{\top} C U\right) \leq(1+\epsilon)\left(Z+U^{\top} C U\right)
$$

Therefore because $Z+U^{\top} C U$ and $\widetilde{Z}+U^{\top} C U$ are positive semi-difinite matrices,

$$
\begin{equation*}
\frac{1}{1+\epsilon}\left(Z+U^{\top} C U\right)^{-1} \leq\left(\widetilde{Z}+U^{\top} C U\right)^{-1} \leq \frac{1}{1-\epsilon}\left(Z+U^{\top} C U\right)^{-1} \tag{10}
\end{equation*}
$$

Moreover by Sherman-Morrison-Woodbury identity,

$$
\begin{equation*}
\left(\widetilde{Z}+U^{\top} C U\right)^{-1}=\widetilde{Z}^{-1}-\widetilde{Z}^{-1} U\left(C^{-1}+U^{\top} \widetilde{Z}^{-1} U\right)^{-1} U^{\top} \widetilde{Z}^{-1} \tag{11}
\end{equation*}
$$

The result follows by combining 10 and 11 .

## 5 Accessing the sparse block-Krylov inverse

In this section, we formalize, with error bounds, the type of access one has to the inverse of projection operator defined from sparse matrix. Specifically, we describe the running time of solving a sparse matrix against a batch of vectors as stated in Theorem 7. The statements below are closely based on the top-level claims in $[25]^{1}$

Proof of Theorem 7. Since $A W A^{\top}$ is already symmetrized, we can ignore the outer step involving a multiplication by the transpose of an asymmetric matrix. So we will show how to give access to an operator $Z_{A W} A^{\top}$ such that

$$
\begin{equation*}
\left\|Z_{A W A^{\top}}-\left(A W A^{\top}\right)^{-1}\right\|_{F} \leq \epsilon \tag{12}
\end{equation*}
$$

The algorithm that computes access to this $Z$ was given in Section 7 of [25].

1. Perturb with random Gaussian $R$ to form the perturbed matrix

$$
\widehat{A}=A W A^{\top}+R
$$

2. Generate Krylov space with $\tilde{O}(m)$ extra columns,

$$
K=\left[\begin{array}{lllll}
G^{S} & \widehat{A} G^{S} & \widehat{A}^{2} G^{S} & \ldots & \widehat{A}^{m-1} G^{S}
\end{array}\right],
$$

which is padded with a dense, $n$-by- $n-m s$ dense Gaussian $G$ to form $Q=[K, G]$.
3. Replace the inverse of the block Krylov space portion, $H=K^{\top} \widehat{A} K$ using the block-Hankel inverse.
4. Complete the inverse using another Schur complement / low rank perturbation, and further multiplications by $Q$ on the outside.

Specifically, for step (3), the $Z_{H}$ generated by the block-Hankel solver is the product of two explicit matrices, each with $\tilde{O}(m \log (\kappa))$ bits,

$$
Z_{H}=X_{H} Y_{H}
$$

such that the cost of computing $X_{H} B, Y_{H} B, X_{H}^{\top} B, Y_{H}^{\top} B$ for some $s m$-by- $r$ matrix $B$ with up to $\tilde{O}(m \log \kappa)$ bits per entry is $\tilde{O}\left(m^{2} \log \kappa \operatorname{MM}\left(\frac{n}{m}, \frac{n}{m}, r\right)\right)$ by Lemma 6.6 of $[25]^{1}$,

Then in step (4), $Z_{H}$ is extended to the full inverse for $A W A^{\top}, Z_{A W A^{\top}}$, via the operator:

$$
Z_{A W A^{\top}}=Q\left[\begin{array}{c|c}
I & Z_{H G}  \tag{13}\\
\hline 0 & I
\end{array}\right]\left[\begin{array}{c|c}
Z_{H} & 0 \\
\hline 0 & Z_{G G}
\end{array}\right]\left[\begin{array}{c|c}
I & 0 \\
\hline Z_{G H} & I
\end{array}\right]
$$

where the intermediate matrices $Z_{G H}, Z_{G G}$, and $Z_{H G}$ are given by:

$$
\begin{equation*}
Z_{G H}=Z_{H G}^{\top}=-(\widehat{A} G)^{\top} \widehat{A} K Z_{H} \tag{14}
\end{equation*}
$$

[^1]\[

$$
\begin{equation*}
Z_{G G}=\left[(\widehat{A} G)^{\top} \widehat{A} G-(\widehat{A} G)^{\top} \widehat{A} K Z_{H}(\widehat{A} K)^{\top} \widehat{A} G\right]^{-1} \tag{15}
\end{equation*}
$$

\]

The last block has size $\tilde{O}(m)$, so the blocks get explicitly computed. We can also extract out its effect, and treat it as a separate perturbation to the overall matrix:

$$
Z_{A W A^{\top}}=Q\left(Z_{H}+\left[\begin{array}{c|c}
Z_{H G} Z_{G G} Z_{G H} & Z_{H G} Z_{G G} \\
\hline Z_{G G} Z_{G H} & Z_{G G}
\end{array}\right]\right)(\widehat{A} Q)^{\top} .
$$

Here we overloaded notation by extending $Z_{H}$ onto the full coordinates (filling the extra with 0 s).
Observe the second matrix is

$$
\left[\begin{array}{c}
Z_{H G} \\
I
\end{array}\right] Z_{G G}\left[\begin{array}{ll}
Z_{G H} & I
\end{array}\right]
$$

(this is, in fact, excatly what Sherman-Moorison-Woodbury gives). So we can treat the whole thing as a rank- $\tilde{O}(m)$ perturbation to $Z_{H}$. Substituing in the factorization of $Z_{H}$ as $X_{H} Y_{H}^{\top}$, we get back

$$
\left.Z_{A W A^{\top}}=\left[\begin{array}{ll}
X_{H} & {\left[\begin{array}{c}
Z_{H G} \\
I
\end{array}\right] Z_{G G}}
\end{array}\right]\left[\begin{array}{cc}
Y_{H} & \\
{\left[Z_{G H}\right.} & I
\end{array}\right]\right]
$$

The cost of multiplying $Z$ against a $n$-by- $r$ matrix $B$ is then broken down into three parts:

1. The cost of multiplying $Y_{H}$ against an $s m$-by- $r$ matrix: by Lemma 6.6 of $[25]^{1}$, this takes time $\tilde{O}\left(\left(\frac{n}{m}\right)^{\omega} m^{2} \log \kappa\right)$.
2. The cost of multipling $X_{H}$ against an $s m$-by- $r$ matrix, with $\tilde{O}(m \log \kappa)$ extra bits in the numbers. This takes the same time as above, since both $X_{H}$ and $Y_{H}$ already have $\tilde{O}(m \log \kappa)$ bits in their entries.
3. Multiplying the extra matrices $Z_{H G}, Z_{G G}$, and $Z_{G H}$ : these are $\tilde{O}(m)$-by- $n$ matrices (with $\tilde{O}(m \kappa)$ bits per number), so the running times are lower order terms by the assumption of $m<n^{1 / 4}$.
4. Mutliplying $n$-by- $r$ matrices with $\tilde{O}(m \log (\kappa))$ bits by $Q$ and $(A Q)^{\top}$ : this has two parts: multiplying by $G^{S}$, and by a degree $m$ polynomial in $\widehat{A}$. The former's cost is at most $O\left(n^{2} m^{3}\right)$ by the sparsity bound on $G^{S}$, while the latter's cost is the cost of $O(m r)$ matrix-vector multiplies in $A$ against vectors with $m \log \kappa$ bits.
